Haem homeostasis is regulated by the conserved and concerted functions of HRG-1 proteins

Abbhirami Rajagopal1, Anita U. Rao1, Julio Amigo2, Meng Tian3, Sanjeev K. Upadhyay4, Caitlin Hall1, Suji Uhm1, M. K. Mathew4, Mark D. Fleming5, Barry H. Paw2, Michael Krause5 & Iqbal Hamza1

Haems are metalloporphyrins that serve as prosthetic groups for various biological processes including respiration, gas sensing, xenobiotic detoxification, cell differentiation, circadian clock control, metabolic reprogramming and microRNA processing5. With a few exceptions, haem is synthesized by a multistep biosynthetic pathway comprising defined intermediates that are highly conserved throughout evolution5. Despite our extensive knowledge of haem biosynthesis and degradation, the cellular pathways and molecules that mediate intracellular haem trafficking are unknown. The experimental setback in identifying haem trafficking pathways has been the inability to dissociate the highly regulated cellular synthesis and degradation of haem from intracellular trafficking events6. Caenorhabditis elegans and related helminths are natural haem auxotrophs that acquire environmental haem for incorporation into haemoproteins, which have vertebrate orthologues2. Here we show, by exploiting this auxotrophy to identify HRG-1 proteins in C. elegans, that these proteins are essential for haem homeostasis and normal development in worms and vertebrates. Depletion of hrg-1, or its paralogue hrg-4, in worms results in the disruption of organisal haem sensing and an abnormal response to haem analogues. HRG-1 and HRG-4 are previously unknown transmembrane proteins, which reside in distinct intracellular compartments. Transient knockdown of hrg-1 in zebrafish leads to hydrocephalus, yolk tube malformations and, most strikingly, profound defects in erythropoiesis—phenotypes that are fully rescued by worm HRG-1. Human and worm proteins localize together, and bind and transport haem, thus establishing an evolutionarily conserved function for HRG-1. These findings reveal conserved pathways for cellular haem trafficking in animals that define the model for eukaryotic haem transport. Thus, uncovering the mechanisms of haem transport in C. elegans may provide insights into human disorders of haem metabolism and reveal new drug targets for developing anthelminthics to combat worm infestations.

In animals, the terminal enzyme in haem synthesis, ferrochelatase, is located on the matrix side of the inner mitochondrial membrane6. Most newly synthesized haem must be transported through mitochondrial membranes to haemoproteins found in distinct intracellular membrane compartments6. Haem synthesis is regulated at multiple steps by effectors including iron, haem and oxygen to prevent the uncoordinated accumulation of haem or its precursors6. C. elegans is a haem auxotroph and is therefore a unique genetic animal model in which to identify the molecules and delineate the cellular pathways for eukaryotic haem transport6. Haem analogue studies have suggested that a haem uptake system exists in C. elegans6. Synchronized C. elegans cultures grown in axenic mCeHR-2 liquid medium9 and supplemented with haemin chloride revealed a robust uptake of fluorescent zinc mesoporphyrin IX (ZnP) at a haem concentration of 20 μM or less, in contrast with worms grown at 100 μM haem or more (Fig. 1a, b), suggesting that the transport and accumulation of haem are regulated.

We conducted genome-wide microarrays to identify genes that are transcriptionally regulated by haem. Wild-type N2 worms were grown for two synchronized generations in 4 μM (low), 20 μM (optimal) and 500 μM (high) haem concentrations in liquid medium and their messenger RNA was hybridized to Affymetrix C. elegans genome arrays. Statistical analyses identified changes in 370 genes, of which about 164 had some sequence identity to genes in the human genome databases at the amino-acid level, and more than 90% of the genes had no functional annotation in the C. elegans database (Supplementary Table 1).

We postulated that the expression of genes that encode for haem transporters might be elevated during haem deficiency to maximize uptake of dietary haem. To identify candidate haem transporter genes, we sorted the 117 genes to identify those that were specifically upregulated in low haem (Supplementary Table 1, categories 1 and 2) and encoded for proteins with predicted transmembrane domains, transport functions, and/or haem/metal-binding motifs. F36H1.5 was >10-fold upregulated at low haem but was undetectable at 500 μM haem, and the predicted open reading frame of 169 amino acids (>19 kDa) showed similarities to high-affinity permease transporters8. We refer to F36H1.5 as haem responsive gene-4 (hrg-4). RNA blotting and qRT–PCR analysis revealed that hrg-4 mRNA was significantly upregulated (>40-fold) at 4 μM haem but undetectable at 20 and 500 μM haem (Fig. 1c, d). We identified three putative paralogues of hrg-4 in the C. elegans genome; we termed them hrg-1 (R02E12.6), hrg-5 (F36H1.9) and hrg-6 (F36H1.10), with 27%, 39% and 35% overall amino-acid sequence identity, respectively (Fig. 1e and Supplementary Fig. 1a). Although both hrg-1 and hrg-4 were highly responsive to haem deficiency (Fig. 1c), the magnitude of change in mRNA expression at 1.5 μM haem and their responsiveness to haem-mediated repression were markedly different (Fig. 1d and inset). By contrast, hrg-5 and hrg-6 expression seemed to be constitutive and not regulated by haem (not shown). hrg-4, hrg-5 and hrg-6 are nematode-specific genes, whereas hrg-1 has orthologues with about 25% amino acid identity in vertebrates (Fig. 1e, f, and Supplementary Fig. 1). Topology modelling and motif analysis of HRG-1 identified four predicted transmembrane domains (TMDs) and a conserved tyrosine and acidic-dileucine-based sorting signal in the cytoplasmic carboxy terminus (Fig. 1e and Supplementary Fig. 1a)11. In addition, residues that could potentially either directly bind haem (H90 in TMD2) or interact with the...
haem side chains (FARKY) were situated in the C-terminal tail (Fig. 1e, g)\(^{12-14}\).

To study the function of hrg-1 genes in haem homeostasis, we generated a hrg-1::gfp transcripational fusion in C. elegans. hrg-1::gfp was expressed specifically in the intestinal cells in larvae and adults (Fig. 2a). Its expression was regulated by feeding transgenic worms sequentially with Escherichia coli that had been grown on agar plates with or without exogenous haem (Fig. 2a). hrg-1 repression was specific to haem because neither protoporphyrin IX nor iron altered the expression of hrg-1::gfp (Fig. 2b). We next assessed the effect of HRG-1 and HRG-4 depletion in worms by RNA-mediated interference with three independent assays: first, the expression of green fluorescent protein (GFP) in the hrg-1::gfp haem sensor strain to monitor haem homeostasis; second, the accumulation of fluorescent ZnMP as a function of haem uptake; and third, animal viability in the presence of a cytotoxic haem analogue, gallium protoporphyrin IX (GaPP)\(^{7}\). Knockdown of hrg-4 by RNAi resulted in the expression of hrg-1::gfp, even though haem levels sufficient to suppress GFP were present in the diet (Fig. 2c). hrg-4 RNAi resulted in no detectable accumulation of ZnMP fluorescence in worms that were grown in 1.5 mM haem, a concentration that is sufficient to induce a robust uptake of haem (Fig. 2d). Consistent with these findings was our observation that progeny from hrg-4 RNAi worms were also markedly resistant to GaPP toxicity (Fig. 2e), in concordance with recent genome-wide studies revealing hrg-4 expression in the worm intestine\(^{15}\). In contrast, hrg-1 RNAi showed a significant derepression of GFP only at low haem levels in the hrg-1::gfp haem sensor strain (Fig. 2c), but no discernible effect on animal viability assessed with GaPP toxicity assays (Fig. 2e). We found that the intensity of ZnMP fluorescence was significantly greater in the intestines of HRG-1-depleted worms than in controls (Fig. 2d and Supplementary Fig. 2). The observed differences in RNAi phenotypes of hrg-4 and hrg-1 suggest that haem uptake into worm intestinal cells involves HRG-4, whereas HRG-1 mediates haem homeostasis by means of an intracellular compartment.

To dissect HRG-1 function in a vertebrate genetic model, we used zebrafish (Danio rerio). We reasoned that any perturbation in haem homeostasis would be manifested as haematological defects in the fish embryo\(^{16}\). BLAST searches revealed an orthologous gene on zebrafish chromosome 6 that shared about 21% amino acid identity with C. elegans HRG-1. Whole-mount in situ hybridization of zebrafish embryos at the 15somite stage and 24 h after fertilization showed zebrafish hrg-1 mRNA expressed throughout the embryo, including the central nervous system (Fig. 3a). To knock down hrg-1 in zebrafish, antisense morpholinos (MO2) were designed at the splice junctions to selectively induce hrg-1 mRNA mis-splicing and degradation. Embryos injected with MO2 had severe anaemia and lacked any detectable o-dianisidine-positive erythroid cells (Fig. 3b, c). MO2 morphants showed other developmental defects, including hydrocephalus and a curved body with shortened yolk tube.

The phenotypes observed in hrg-1 knockdown embryos suggested an essential role for zebrafish hrg-1 in the specification, maintenance or maturation of the erythroid cell lineage. hrg-1 morphants revealed wild-type levels of flt1–globin mRNA, a marker for haemoglobinization in the developing blood island and intermediate cell mass of embryos at 24 h after fertilization, but by 48 h after fertilization there were no detectable globin-producing cells (Supplementary Fig. 3a).

---

**Figure 1** Identification of hrg-1 and hrg-4 in C. elegans. a, Fluorescent ZnMP (40 µM for 3 h) accumulation in worms grown in mCeHR-2 medium supplemented with 1.5 µM (left) and 500 µM (right) haem. Differential interference contrast (DIC, top) and rhodamine fluorescence (bottom). b, Total mean fluorescence intensity (filled circles) of ZnMP accumulated in worms (40 µM for 3 h) after 9 days of growth in mCeHR-2 medium supplemented with the indicated haem concentrations. Open diamonds, growth of worms in haemin. Results are means ± s.d. \(n = 100\). c, Northern blot analysis of hrg-1 and hrg-4 expression in response to 4 and 20 µM haem in mCeHR-2 medium. The blot was stripped and reprobed with glyceraldehyde 3-phosphate dehydrogenase (gpd-2) as loading control, kb, kilobases. d, Expression of hrg-4 (circles) and hrg-1 (squares) mRNA estimated by quantitative RT–PCR from total RNA obtained from worms grown at the indicated haem concentrations. Each data point shows mean ± s.d. and the results are representative of three separate experiments. Inset: mRNA levels at higher haem concentrations. e, Multiple sequence alignment of C. elegans HRG-1 with its vertebrate orthologues. Asterisk, histidine (H90); circles, aromatic amino acids; box, putative transmembrane domains; YXXx, C-terminal tyrosine motif; D/E, dileucine motif. f, Phylogenetic analysis of HRG-1 proteins using the neighbour-joining method. g, Predicted topology of C. elegans HRG-1 showing H90 in TMD2, and FARKY, the putative haem-interacting motif, in the cytoplasmic tail.
Moreover, markers for myeloid (MPO and L-plastin) and thrombocyte (platelet-equivalent, cd41) lineages were normal in the hrg-1 morphant embryos (Supplementary Fig. 3b, c). These findings indicate that zebrafish hrg-1 is not required for cell lineage specification but rather for maintenance and haemoglobinization of the embryonic erythroid cells. Similarly, pax 2.1 mRNA expression, a marker of the midbrain/hindbrain boundary organizer, was severely deficient in the central nervous system of MO2 morphants, indicating that midbrain–hindbrain development in zebrafish is also dependent on hrg-1 (Supplementary Fig. 3d). To verify whether the knockdown phenotypes observed in zebrafish corresponded functionally to the RNAi phenotypes in C. elegans (compare Fig. 2c–e with Fig. 3b, c), we co-injected MO2 in the presence and absence of C. elegans hrg-1 synthetic antisense RNA (cRNA). Despite the modest (21%) sequence identity between the C. elegans and zebrafish HRG-1, more than 85% of the morphant embryos were fully rescued by Cehrg-1 (95 of 108 mutants rescued), in contrast with none for the control embryos (0 of 194 mutants rescued), correcting the defects in anaemia, hydrocephalus and body axis curvature (Fig. 3d, e). These studies suggest that C. elegans and zebrafish HRG-1 have a highly conserved function in modulating haem homeostasis.

To dissect the function of HRG-1 in vertebrates further, we examined its gene expression, intracellular localization and biochemical properties in mammalian cells. Genome database searches with HHRG-1 identified an orthologous gene, which we refer to as hHRG-1 (Fig. 1e), with about 23% and 65% identity to worm and zebrafish HRG-1 proteins, respectively. hHRG-1 has a highly conserved function in modulating haem properties in mammalian cells. Genome database searches with C. elegans HRG-1 identified an orthologous gene, which we refer to as CeHRG-1 and CeHRG-4, CeHRG-1 and hHRG-1 to haem (Fig. 4e), whereas little imolation that HRG-1 and HRG-4 may interact with haem. Haemin-agarose affinity chromatography performed on cell lysates from transiently transfected HEK-293 cells showed significant binding of CeHRG-4, CeHRG-1 and hHRG-1 to haem (Fig. 4e), whereas little binding was observed for human ZIP4, an eight-transmembrane-domain zinc transporter that localizes to the plasma membrane and perinuclear cytoplasmic vesicles. Because HRG-1 localized to endosomal–lysosomal organelles whereas HRG-4 is on the plasma membrane.

Figure 2 | hrg-1 and hrg-4 are essential for haem homeostasis in C. elegans. a, IQ6011 hrg-1::gfp ‘haem sensor’ strain responds to exogenous haem after sequential exposure to E. coli grown on agar plates in the absence (left and right) and presence (middle) of 200 µM haem. UTR, untranslated region. b, Spectrofluorimetric measurements of GFP in worm lysates from IQ6011 strain grown in the presence of indicated concentrations of haem plus 20 µM protoporphyrin IX (PPIX) or 1 mM FeCl3. Each data point shows mean ± s.d. and the results are representative of three separate experiments. c–e, Depletion of hrg-1 or hrg-4 in worms by RNAi with feeding bacteria. d, Dysregulation of GFP (means ± s.e.m.; n = 35–45 worms per treatment) in IQ6011 when fed with bacteria grown in the presence of 0.5 and 25 µM haem. Values with different letter labels are significantly different (P < 0.001) within each treatment. d, Aberrant ZnMP fluorescence accumulation in worms fed with 10 µM ZnMP for 16 h. Scale bar, 50 µm. e, Differences in viable progeny (mean ± s.d.; n = 30 P0 worms per treatment) after 5 days of exposure to 1 µM GaPP plus RNAi bacteria. Filled bars, viable eggs; open bars, larvae. The results for c–e are representative of at least four separate experiments.

membrane, we reasoned that these proteins may bind haem as a function of pH. In a manner consistent with their localization, haem binding to HRG-1 was significantly decreased by increasing the pH, in contrast with HRG-4, which bound haem over a broader pH range (Fig. 4e, lanes 3 and 6). These binding assays, together with the intracellular localization results, correlate directly with the phenotypic differences observed in worms in which hrg-1 and hrg-4 were knocked down by RNAi (Fig. 2c–e).

We next investigated whether HRG-1 proteins mediate haem uptake, by expressing hHRG-1 ectopically in MEL cells. ZnPMP uptake or retention was substantially altered in MEL cells constitutively expressing hHRG-1 in comparison with control cells; maximal differences were observed after 30 min of incubation (Fig. 4f and Supplementary Fig. 7). To assay haem transport directly, Xenopus laevis oocytes were injected with cRNA and haem-dependent currents were monitored under a two-electrode voltage clamp. Significant inward currents of over 250 nA were observed when 20 μM haem was added to oocytes clamped at −110 mV and injected with cRNA for CeHRG-1, hHRG-1 and CeHRG-4; this is indicative of haem-dependent transport across the plasma membrane (Fig. 4g and Supplementary Fig. 8). Together, these results show that the worm and mammalian HRG-1 proteins transport haem.

Initiation of haem homeostasis genes

Given the parallels between copper, iron and haem in their biochemical reactivity and toxicity, we envisage an intricate cellular network of haem homeostasis molecules that bind, transfer and compartmentalize haem.6,22,23 We propose a model of haem homeostasis in which CeHRG-4 mediates haem uptake in C. elegans at the plasma membrane, whereas CeHRG-1 facilitates intracellular haem availability through an endosomal and/or lysosome-related compartment. The model does not exclude the possibilities that CeHRG-1 traffics through the plasma membrane and may be functional on the cell surface.

Figure 4 | Expression, localization and functional studies of worm and mammalian hrg-1. a, b, mRNA expression of human HRG-1 in multiple adult human tissues (a; PBL, peripheral blood leukocytes) and human tissue-derived cell lines (b). The blot was stripped and reprobed with β-actin as loading control. c, Expression of C-terminally tagged proteins in transfected HEK-293 cells by SDS–PAGE and immunoblotting with antibodies against HA (lanes 1–3, 30 μg) and GFP (lanes 4–6, 25 μg), or by in vitro expression with 35S fluorography (lanes 7–9, one-fifth of total extract). d, Cellular localization of C-terminally tagged fluorescent proteins in transfected HEK-293 cells by confocal microscopy. The plasma membrane (PM) was identified using wheatgerm agglutinin. Scale bar, 20 μm. e, HRG-1 proteins interact with haem as a function of pH. Cell lysates (lanes 1 and 4, one-tenth of total protein) from HEK-293 cells expressing the indicated HA-tagged proteins were incubated with haemin-agarose. Wash (lanes 2 and 5) and harvest (lanes 3 and 6) of the protein-agarose column. Samples were subjected to SDS–PAGE followed by immunoblotting with anti-HA antisera. f, Flow-cytometry histograms show enhanced ZnPMP uptake and accumulation after 30 min of incubation with 5 μM ZnPMP in MEL cells stably expressing either hHRG-1–HA (right) or empty vector (left). g, Electrophysiological currents (means ± s.d., n = 4) elicited from Xenopus oocytes injected with cRNA encoding the indicated protein, when clamped at −110 mV in the presence of 20 μM haem chloride. The y axis represents the difference in current in the presence and absence of haemin, normalized to the current observed in the absence of haem. Values with different letter labels are significantly different (P < 0.05) within each treatment compared with hKv1.1 control. h, Proposed model for the function of HRG-1 proteins in haem homeostasis in C. elegans intestinal cells. CeHRG-4 mediates haem uptake through the plasma membrane, whereas CeHRG-1 facilitates intracellular haem availability through an endosomal and/or lysosome-related compartment. The model does not exclude the possibilities that CeHRG-1 traffics through the plasma membrane and may be functional on the cell surface.

METHODS SUMMARY

C. elegans strains were grown either in liquid mCeHR-2 medium or on Nematode Growth Medium agar plates spotted with E. coli. Cell lines were routinely cultured in basal growth medium composed of DMEM and 10% bovine serum. We maintained zebrafish on a standard genetic AB or Tu wild-type background. For microarray analysis, synchronized F2 larvae were re-inoculated in mCeHR-2 medium supplemented with 4, 20 or 500 μM haemin and harvested at the late L4 stage for hybridization to an Affymetrix C. elegans Whole Genome Array. C. elegans hrg-1 putative promoter was cloned into pPD95.67 to create a hrg-1::gfp transcriptional fusion (strain IQ6011). For
RNAi experiments, equal numbers of IQ6011 synchronized F1 L1 larvae were placed on NGM agar plates containing 2 mM isopropyl β-D-thiogalactoside and spotted with RNAi feeding bacteria that had been grown in Luria–Bertani broth supplemented or not with haemin for 5.5 h. For GFP measurements, worms were harvested and lysed to quantify GFP fluorescence with an ISS PCI spectrophotometer. Pull-down assays of transfected HEK-293 cells were performed with equivalent amounts of target protein and 300 nmol of haemin–agarose. For confocal microscopy studies, a Zeiss laser scanning LSM 510 equipped with argon and HeNe lasers was used. For zebrafish experiments, whole-mount in situ hybridization was performed with digoxigenin-labelled cRNA probes in accordance with standard protocols. Live embryos at 48–72 h after fertilization were stained for haemoglobinized cells with α-dianisidine. Zebrafish hrg-1 gene rescue assays were performed by injecting 1.5 ng of MO2 morpholino together with 200 pg of C. elegans hrg-1 cRNA. For flow cytometry, MEL cells stably expressing HRG-1 were incubated with 5 μM ZnMP and the fluorescence intensity was measured by flow cytometry. Electrophysiological measurements in Xenopus oocytes injected with cRNA were performed with a two-electrode voltage clamp.

Figures

**Fig. S1:** Sequence analysis of HRG-1 proteins. *(a)* Multiple sequence alignment of CeHRG-1, -4, -5 and -6 paralogs obtained using ClustalW (v. 1.83). Identical amino acids and conservative changes are indicated by reversed and shaded characters, respectively. Boxed residues denote the four putative transmembrane domains based on predictions from HRG-1. C-terminus tyrosine (Yxxφ) and di-leucine (D/ExxxLL) based sorting motifs in HRG-1 are indicated. Notably, HRG-4 lacks both sorting signals and residue H90 (asterisk) in TMD2 is substituted with a tyrosine (Y63). Unlike histidines, tyrosine heme ligands have a lower redox potential and the coordination stabilizes heme from carrying out oxidative chemistry. *(b)* The maximum parsimony phylogram of HRG-1 proteins from different species implemented using PHYLIP (v. 3.6).

**Fig. S2:** ZnMP fluorescence accumulation in *hrg-1* and *hrg-4* RNAi worms. Total mean fluorescence intensity of ZnMP was calculated in $\approx 50$ worms from each RNAi treatment by epifluorescence microscopy and SimplePCI software. Each data point represents the mean $\pm$ SEM and the results are representative of three separate experiments. All values are significantly different ($P<0.05$), as determined by using a one-way ANOVA with Student–Newman–Keuls multiple comparisons test.
Fig. S3. Loss of hrg-1 affects on zebrafish erythropoiesis. (a) Whole mount in situ hybridization for βe1-globin mRNA in wild type and hrg-1 MO2 morphants. Loss of hrg-1 results in a failure to maintain embryonic erythroid cells. (b) Analysis of myelopoiesis in hrg-1 morphant embryos. Myeloid cells were analyzed by whole mount in situ hybridization with myeloid-lineage markers, myeloperoxidase (MPO) and L-plastin, in wild type and hrg-1 morphant embryos at 48 hpf. No significant differences in the expression of MPO and L-plastin mRNA were noted between wild type control and morphant embryos. Inset: higher magnification views of the L-plastin staining cells (arrows). (c) Analysis of thrombopoiesis in hrg-1 morphant embryos. Morpholinos targeting hrg-1 were microinjected into transgenic Tg(CD41:GFP) embryos in which thrombocytes (platelet-equivalent cells) were specifically tagged with green fluorescence protein (GFP). No significant differences in the number of circulating GFP+ thrombocytes (arrows) were appreciated in hrg-1 morphants compared to wild type controls at 4 dpf. (d) Whole mount in situ hybridization for pax2.1 mRNA. Loss of hrg-1 in MO2 morphants results in a failure to form proper mid- and hind-brain structures.

Fig. S4: Quantitation of hHRG-1 mRNA expression in human tissues and cell lines. Relative hHRG-1 mRNA levels from Northern blots of human tissues (a) and cell lines (b) quantitated by ImageQuant v2.2. hHRG-1 mRNA was normalized to β-actin as the loading control.

Fig. S5: Expression pattern of mammalian HRG-1 in cultured cells. (a) Human HRG-1 mRNA levels were unaltered by heme or iron depletion in cultured HEK293 cell lines. Cells were either grown in basal growth medium or in the presence of heme-depleted medium (HD), 500 μM succinyl acetone (SA) to inhibit heme synthesis, and 100 μM desferoxamine (DFO) to chelate iron. After 14 h of heme/iron depletion, cells were exposed to either 50 μM heme or 100 μM iron-SIH for 3 h. Total RNA was
extracted from cells and processed for qRT-PCR using primers designed to amplify cDNA for HRG-1, heme oxygenase (HMOX1) and the transferrin receptor (TfR1). Gene specific fold induction was quantitated by normalizing to GAPDH as the loading control. (***, P < 0.001 and *, P < 0.05 between basal conditions and the indicated treatment). Mean values were calculated, and differences were compared by using a one-way ANOVA with a Student–Newman–Keuls multiple comparison test. (b) Mouse Hrg-1 mRNA is not induced during erythroid maturation in cultured MEL cells. MEL cells (DS19 clones) were induced with 1.5 % DMSO (v/v) which results in appearance of o-dianisidine positive cells, a marker of hemoglobinization. mHrg-1 mRNA was unaltered in MEL cells 72 h post differentiation compared with α-globin (Hba-a1), β-globin (Hbb-b1), and Alas-2 mRNA. (c) Time-dependence of mouse Hrg-1 mRNA expression as a function of erythroid maturation in MEL cells. Hrg-1 expression does not vary during MEL cell differentiation. Total RNA obtained from MEL cells harvested at the specific time points after induction with DMSO were quantitated for Hrg-1 mRNA expression using qRT-PCR and normalized to Gapdh as the loading control. Each data point represents the mean ± SEM and the results are representative of two separate experiments.

**Fig. S6: Intracellular localization of human HRG-1.** Confocal microscopy images of HEK 293 cells plated on coverslips and co-transfected with plasmids containing hHRG-1 tagged with ECFP at the C-termini (left) and the indicated organelle marker tagged with EYFP (right). (Bar = 20 microns).

**Fig. S7: Flow cytometry reveals greater ZnMP fluorescence in MEL cells expressing hHRG-1.** Dot plots with forward scatter (y-axis) and fluorescence intensity (x-axis) show higher percentage of fluorescence-positive cells (right gate with red arrow) in MEL cells stably expressing hHRG-1:HA compared to the control vector, indicating
that the exogenous hHRG-1 increases the efficiency of cellular ZnMP uptake/accumulation.

**Fig. S8: Currents from a Xenopus oocyte expressing CeHRG-4:HA.** Currents elicited from a *Xenopus* oocyte injected with CeHRG-4:HA cRNA in the absence (left) and presence (right) of 20 μM hemin chloride. The oocyte was clamped at -60 mV and stepped to potentials ranging from -110 mV to +50 mV in 20 mV steps. Traces corresponding to steps to -110, -30, +10 and +50 mV are labeled. The horizontal dotted line represents the zero current base line, which also indicates the reversal potential. Scale bars shown are common to both traces. Note the shift in reversal potential indicated by the change in baseline between the two traces (from -30 mV in the absence of hemin to about -10 mV in the presence of hemin), as well as the pre-steady-state transient at high depolarization in the presence of heme.
Supplementary Methods

Biological materials, strains, cDNA Cloning, worm and cell culture. *C. elegans* strains 24 were grown either in liquid mCeHR-2 medium or on NGM agar plates spotted with *E. coli* OP50 or HT115(*DE3*) strains 25. Synchronized L1 larvae were obtained by bleaching P₀ gravid worms grown in liquid mCeHR-2 medium supplemented with 1.5, 10 or 20 µM heme 26. Hemin chloride, zinc mesoporphyrin IX and gallium protoporphyrin IX were purchased from Frontier Scientific, Inc. Plasmids for cloning and injections into worms were part of the Fire Vector Kit (Addgene). *C. elegans hrg-1* and *hrg-4* cDNA were cloned by reverse transcription of total RNA isolated from worms, and amplified by PCR using primers containing *Bam*HI and *Xho*I linkers, either with or without HA epitope tags. Primers designed to amplify worm ORFs were based either on Wormbase predictions or 5' and 3' RACE experiments. Human HRG-1 cDNA (GenBank accession number BC065033) was cloned by RT-PCR from HEK293 cells. The PCR products were ligated into plasmids pCDNA3.1(+) Zeo (Invitrogen) and pEGFP-N1 (Clontech) for expression in mammalian cells, pCS2 + for zebrafish experiments, or pT7TS for *Xenopus* oocyte expression. Cell lines were routinely cultured in basal growth medium composed of DMEM (GIBCO/BRL) and 10 % bovine serum supplemented with penicillin / streptomycin / glutamine. Transient transfections were performed either with Lipofectamine 2000 (Invitrogen) or FuGENE 6 (Roche). The following zebrafish strains were maintained and developmentally staged, as described 27: wild type AB and Tü, and the transgenic line expressing green fluorescent protein under the CD41 promoter, Tg(CD41:GFP) 28. *P* values for statistical significance were calculated by using a one-way ANOVA with Student–Newman–Keuls multiple comparison test by using INSTAT version 3.06 (GraphPad, San Diego).
**RNA isolation and microarray analysis.** Equal numbers of L1 larvae (F1) were inoculated in mCeHR-2 medium with 4, 20 or 500 µM hemin chloride and grown at 20°C. Worms were grown for two synchronized generations and late L4 stage F2 worms from all three heme conditions were harvested at the same developmental stage. Total RNA from three biological replicates were hybridized to Affymetrix *C. elegans* Whole Genome Arrays. Data from worms grown in mCeHR-2 medium with 4 and 500 µM hemin were compared to data from worms grown in 20 µM hemin. Microarray data were verified with the Robust Multichip Average Method (RMA, R package) and MAS 5.0, Affymetrix. As a starting point, we used an initial cut-off of ≥ 1.2 fold-change in mRNA expression for RMA and a ≥ 1.6 fold-change for MAS 5.0 which resulted in the identification of ≈370 genes (82 and 288). Amino acid sequences encoded by the 370 genes were used to determine protein topology (TMHMM 2.0, SOSUI), motifs (ELM, BLOCKS, Pfam), and pathway classification (KEGG). Putative human orthologs were identified by using the 370 worm protein sequences as queries for BLAST searches of the human genome databases and an E-value cut-off of 10^-3. Orthologs for *C. elegans hrg-1* were identified by BLAST searches in WormBase with the HRG-1 ORF. Multiple sequence alignment was performed by ClustalW (v. 1.83) and the maximum parsimony phenograms were created in PHYLIP (v. 3.6) using distance measures from the Jones-Taylor-Thornton matrix model and neighbor-joining method, rooted by designating *S. japonicum* and mouse *Hrg1* as the outgroup for CeHRG-1 orthologs and CeHRG-4 paralogs, respectively. The resulting tree was bootstrapped 1000 times.

**cDNA synthesis, quantitative real-time PCR and RNA blotting.** Primers spanning at least one intron for quantitative real-time PCR (qRT-PCR) were designed using Primer Express (Applied Biosystems) and Beacon designer 4 (Premier Biosoft) software. Two-step qRT-PCR was carried out to confirm the expression patterns of *hrg-1, hrg-4, hrg-5,*
hrg-6 and gpd-2 (internal control). First strand cDNA was synthesized using 2 μg of total RNA using Superscript II First Strand cDNA synthesis kit (Invitrogen). PCR was performed using the iCycler iQ Real-time PCR Detection System (BioRad) with 0.12 U/μl Taq DNA polymerase, 40 nM fluorescein (Invitrogen), and SYBR Green I Nucleic Acid Gel Stain (Invitrogen) diluted 1:10,000 29. Quality of the PCR products was determined by dissociation curve analysis and gel electrophoresis. Each experiment was done in triplicate. Average C_T values were used for 2^ΔΔCt calculations of relative fold changes in gene expression 30. For RNA blot analysis, 10 μg of total RNA from worms was resolved on a 1.5 % formaldehyde agarose gel, transferred to a nylon membrane (Zeta Probe, BioRad) and probed with a 32P-α-dCTP (Amersham Biosciences) labeled cDNA that was generated by random priming (Stratagene). The probes were hybridized to the membrane for 16 h in ULTRAHyb (Ambion), washed and analyzed after 48 h with a PhosphorImager (Molecular Dynamics).

**hrg-1::gfp heme sensor and RNA interference assays.** *C. elegans* hrg-1 putative promoter (≈3 kb upstream of ATG start codon) was cloned into the *Pstl- ApaI* sites of vector pPD95.67 to create a *hrg-1::gfp* transcriptional fusion. Transgenic lines were generated by microinjection of 50 ng/μl of the *hrg-1::gfp* plasmid into wild-type N2 worms along with pRF4 plasmid (*rol-6*) for positive selection of transformants 31. The integrated transgenic strain (IQ6011) was generated using gamma radiation (2500 rads/5 min). *C. elegans* hrg-1 and hrg-4 ORFs were cloned into the *Pstl- HindIII* sites of the L4440 RNAi feeding vector and transformed into *E. coli* HT115(DE3). Equal numbers of IQ6011 synchronized F1 L1 larvae, obtained from P0 worms grown in mCeHR-2 medium plus 10 μM hemin, were placed on NGM agar plates containing 2 mM IPTG and spotted with RNAi feeding bacteria that had been grown in LB broth supplemented with either 5 or 25 μM hemin or no added hemin (0 μM) for 5.5 h. Worms were analyzed 96 h after RNAi feeding with a Leica MZF16A fluorescence stereoscope.
and fluorescence intensity measurements were quantified with SimplePCI v 6.2 (Compix, Inc.). For analysis of ZnMP uptake, equal numbers of IQ6011 synchronized F_1 L1 larvae obtained from P_0 worms grown in mCeHR-2 plus 1.5 µM hemin, were exposed to the RNAi bacteria on NGM plates containing 1 mM IPTG for 60 h followed by exposure to 10 µM ZnMP for 16 h in mCeHR-2 medium containing 1.5 µM hemin. ZnMP fluorescence intensity was measured with a Leica DMIRE2 inverted microscope fitted with a Rhodamine filter and Nomarski optics and image intensity quantified with SimplePCI. GaPP toxicity measurements were performed by exposure of IQ6011 synchronized F_1 L1 larvae, obtained from P_0 worms grown in mCeHR-2 plus 1.5 µM hemin, to RNAi bacteria for 60 h followed by exposure to 1 µM GaPP in the continuous presence of RNAi bacteria on NGM agar plates to sustain knockdown. After 24 h of egg-laying, the P_0 mothers were discarded to prevent additional eggs from being laid. On day 5, the total number of surviving larvae and viable eggs that hatched was counted.

**Immunological analysis and in-vitro translation.** Plasmids were transiently transfected into cultured adherent monolayers of mammalian cells, and were harvested 48 h post-transfection by cell lysis in 20 mM HEPES, pH 7.4/0.5 % Triton X-100/150 mM NaCl supplemented with protease inhibitor cocktail set II (Calbiochem Corp.) on ice for 15 min, followed by centrifugation for 10 min at 16,000 X g at 4ºC. The Bradford (BioRad) method was used to determine protein concentration from all samples. For immunoblotting, lysates were mixed with Laemmli Sample Buffer containing either β-mercaptoethanol or 100 mM DTT without heat denaturation, resolved by SDS-PAGE, and transferred to nitrocellulose membranes for detection by either the SuperSignal West Pico or West Femto Chemiluminescence kits (Pierce) and horseradish peroxidase conjugated secondary antibody (Pierce). Linearized ORFs cloned into pcDNA3.1(+)-zeo were transcribed and translated *in-vitro* in the presence of T7 polymerase, wheat
germ extract, and 22 µCi of [35S]methionine and cysteine using a TNT kit (Promega), according to the manufacturer’s instructions. The reaction product (1/5th) was resolved by SDS-PAGE, and the gels soaked in EnHance (Perkin Elmer) to enhance 35S fluorography, dried, and exposed to a PhosphorImager (Molecular Dynamics). For immunofluorescence experiments, cells grown on glass coverslips were fixed in freshly made 4 % paraformaldehyde and permeabilized in 0.2 % Triton-X 100 as described 32. Coverslips were mounted using ProLong Antifade (Molecular Probes) and analyzed with a PlanApo 60X oil immersion objective on a Leica DMIRE2 inverted microscope. For confocal microscopy studies, a laser scanning Zeiss LSM 510 confocal microscope equipped with Argon (458 and 488), HeNe (543 and 633) and a planApo 100X oil immersion objective was used. Rabbit polyclonal antibody against HA epitope (Sigma) or GFP (Qiagen) were used for immunoblotting or immunofluorescence experiments. In some experiments, cells grown on coverslips were incubated with Alexa 633 conjugated wheat germ agglutinin (Molecular Probes) for 5 min to label the plasma membrane. Organelle marker plasmids were generously provided by Dr. J. Lippincott-Schwartz.

**Worm lysis and GFP measurements.** IQ6011 was grown in mCeHR-2 medium supplemented with 1.5, 4, 20 or 500 µM hemin for two generations. Worms were harvested at 800 X g for 5 min and washed twice with M9 buffer. The final worm pellet was resuspended in M9 buffer with protease inhibitors and lysed with FastPrep-24 (MP Bio) in the presence of Lysing Matrix D beads for 60 s at 6.5 setting. The worm lysates were centrifuged twice at 16,000 X g for 30 min to remove worm debris and 700 µg of the total protein, as measured by the Bradford method, was used to quantify GFP fluorescence. Measurements were obtained at 20ºC using an ISS PC1 spectrofluorometer with 1 mm slit-width at a fixed excitation of 488 nm. Scanning emission spectra (500-600 nm) were obtained for each sample, and graphs were generated using the peak absorbance value of GFP at 506 nm.
**Hemin-agarose pull-down assays.** Transfected HEK293 cells were lysed for 30 min on ice in MS buffer (210 mM mannitol, 70 mM sucrose) and either 10 mM HEPES, pH 6.0 and 7.4, or 10 mM Tris, pH 8.5. The lysates were centrifuged at 100 X g for 5 min, and the post-nuclear supernatant was incubated for 30 min at room temperature in the presence of 300 nmol hemin-agarose, prepared as described 33. The expression of individual proteins was first quantified by immunoblotting total cell lysates with HA antibodies and band intensities measured with Quantity One software, v. 4.5 (BioRad). Equivalent amounts of target protein, corresponding to 60 µg of HRG-1 proteins or 360 µg of hZIP4 cell lysates, were mixed with untransfected HEK293 cell lysates to obtain 500µg of total protein that was used for binding. The binding reaction mixture was centrifuged at 800 X g for 3 min, and the resulting agarose pellets were washed three times with 1 ml of wash buffer (150 mM NaCl, 1 % NP-40, and 50 mM Tris-HCl, pH 8.0). The final pellets were incubated with 8 M urea and Laemmli sample-loading buffer containing 100 mM DTT and frozen for 1 h at -80ºC to elute the bound proteins. Samples were thawed, briefly vortexed, and directly loaded on a 12 % SDS/PAGE. Resolved proteins were transferred to nitrocellulose membranes and processed for chemiluminescence detection. Band intensity measurements showed 300 fold less binding of hZIP4 to hemin-agarose compared to either HRG-4 or HRG-1.

**Heme / iron depletion and MEL cell hemoglobinization studies.** HEK293 cells were treated with heme-depleted medium (DMEM, 10 % heme-depleted FBS, 1% PSG, 0.5 mM succinyl acetone) for 20 h. Heme-depleted serum was generated by treatment with 10 mM ascorbic acid 34. For iron chelation, 100 µM desferroxamine (Sigma) was added to the cells 6 h after addition of the heme-depleted medium. After 14 h incubation, the heme-depleted medium was replaced with medium containing DMEM, 10 % heme-depleted FBS, 1 % PSG, 0.5 mM succinyl acetone, and either 50 µM heme or 100 µM Fe-SIH and allowed to incubate for an additional 3 h. A 50 µM heme-replete medium
was generated by mixing 10 mM hemin chloride and 1 mg/ml BSA stock solution with tissue culture medium and incubated overnight at 4ºC. For iron stock solution, 5 mM ferric citrate was mixed with 5 mM SIH (salicylaldehyde isonicotinoyl hydrazone) in 1:2 ratio to generate Fe-SIH \(^{35}\). Cells were washed once with PBS, and total RNA was extracted using Trizol. Extracted RNA samples were treated with TurboDNase (Ambion). Total RNA (2 µg) from each sample was used for cDNA synthesis (iScript cDNA synthesis kit, BioRad). qRT-PCR was performed using primers for hHMOX1, hTfR1 and hHRG1. Fold change was calculated using the \(2^{-\Delta\Delta Ct}\) method. Primers: hHMOX1, sense 5’-ATGACACCAAGGACCAGAGC and anti-sense 5’-TAAGGACCCATCGGAGAAGC, hTfR1, sense 5’-TGAATTGAACCTGGACTATGAGAG and anti-sense 5’-CTGGAAGTAGCAGGGGAAAGAG, hHRG1, sense 5’-CTTCGTGGGCGTCCTCTTCTC and anti-sense 5’-CTTCGT GGGCGTCCTCTTCTC. MEL cells (DS19 clones) were cultured in DMEM, 10 % FBS, 1 % PSG, and 1% non-essential amino acids (Invitrogen). The cells were induced with 1.5 % DMSO. After 4 days of induction, the cells were harvested and RNA was isolated. For the time-course study, cells were harvested every 12 h for a 72 h period after induction with DMSO. The cell pellets for RNA extraction were quick frozen in Trizol. Total RNA was extracted from all samples and treated with DNase as per manufacturer’s instructions. qRT-PCR was performed on cDNA synthesized (First strand cDNA synthesis kit, Invitrogen) using 2 µg of total RNA from each of the samples. Quantitative analysis was done using the \(2^{-\Delta\Delta Ct}\) method. To generate stable clones in MEL cells, 20 µg of pcDNA3.1-Zeo plasmids was linearized with \(Bgl\) II and electroporated into 4 x 10^6 cells. Cells were subjected to 300 µg/ml of zeocin selection for 10 days 48 h post-electroporation. Individual zeocin-resistant clones were isolated and screened by immunoblotting with HA antisera to identify stably expressing cell lines.
**Flow cytometry.** MEL cells stably expressing HRG-1 were incubated with 5 µM ZnMP for 0, 15, 30, 45, and 60 min in uptake medium (25 mM HEPES, pH 7.4, 130 mM NaCl, 10 mM KCl, 1 mM CaCl₂, 1 mM MgSO₄ and 2.5 µM BSA) and the fluorescence intensity of ZnMP accumulated within the cells was measured by flow cytometry (BD FACS caliber) in the FL3 channel using forward and side scatter.

**Zebrafish experiments.** Whole mount *in situ* hybridization (ISH) was performed on wild type and hrg-1 morphants with βα1-globin, gata1 and pax2.1 cDNA probes according to standard protocols. Digoxigenin (DIG)-labeled antisense cRNA probes for myeloperoxidase (MPO) and L-plastin were detected with nitro-blue tetrazolium/5-bromo-4-chloro-3-indolyl phosphate (NBT/BCIP). Live embryos at 48-72 hpf were stained for hemoglobinized cells with o-dianisidine as described. For morpholino knockdowns and rescues with cRNA, two different splicing anti-sense morpholinos, targeting zebrafish hrg-1 gene (GenBank BC053186.1), were synthesized by GeneTools (Philomath, OR). MO1 was complementary to the splice-donor site of exon2:intron2: 5’-CAGCCAAGGAATTACCTGATAATC-3’. MO2 was complementary to the splice-acceptor site intron2:exon3: 5’-CCATAATGCCAAAACCTCC TGAAAAA-3’. Injected and control embryos were fixed at 24 and 48 hpf for whole mount ISH and o-dianisidine staining. *C. elegans hrg1* was subcloned into pCS2+ vector and linearized for synthesis of 5’-capped cRNA using the SP6 mMessage mMachine kit (Ambion). Fertilized zygotes at the 1-cell stage from wild-type zebrafish were injected with empirically pre-determined concentrations of either 5 ng MO1 or 1.5 ng MO2. Rescue assays were performed by co-injecting 1.5 ng MO2 with 200 pg of *C. elegans hrg-1* cRNA. Injected embryos were allowed to develop to 2-3 days post-fertilization (dpf), then stained with o-dianisidine for hemoglobinized cells. For RNA isolation and semi-quantitative RT-PCR, total RNA was isolated from embryos at 24, 48, and 72 hpf (Qiagen) and RNA integrity was confirmed by staining.
with ethidium bromide for 18S/28S rRNA in a 1% agarose gel. For semi-quantitative RT-PCR, first strand cDNA was generated using 1 µg total RNA, 200 U Superscript III reverse transcriptase (Invitrogen), and zebrafish hrg-1 specific primers (available on request). Aberrant hrg-1 mRNA spliceforms in morphants compared to control embryos were determined by RT-PCR, and the respective products resolved on agarose gels. Primers encompassing exon 4 were used as an internal control. Live Tg(CD41:GFP) control and morphant embryos were mounted in 2.5% methylcellulose. Fluorescence images were acquired with an Orca IIER CCD camera (Hamamatsu City, Japan) mounted on a Nikon microscope equipped with a 10X objective (NA 1.4). Electronic shutters and image acquisition were under the control of Metamorph software (Molecular Devices, Downington, PA).

**Electrophysiological measurements in Xenopus oocytes.** HRG ORFs were subcloned into the pT7TS vector and capped polyadenylated RNA transcribed from the T7 promoter using the mMessage mMachne kit (Ambion). Methods of Xenopus oocyte retrieval and their maintenance have been previously described \(^{40}\). RNA injection, two-electrode voltage clamp of Xenopus oocytes and data analysis were carried out as described \(^{40}\), except that a Dagan TEV-200 amplifier was used and the data digitized at 0.1 - 1 kHz.
Supplementary Notes

Gene expression profiles were categorized based on the fold changes relative to 20 μM heme samples. *Summary of genes that showed change in their expression profiles in response to heme determined by MAS 5.0 and RMA methods. §Human orthologs were identified using BLAST with E-value ≤10⁻³.
